2 ABSTRACT

To gain a detailed understanding of how plant microbes evolve and adapt to hosts, pesticides, and other factors, knowledge of the population dynamics and evolutionary history of populations is crucial. Plant pathogen populations are often clonal or partially clonal which requires different analytical tools. With the advent of high throughput sequencing technologies, obtaining genome-wide population genetic data has become easier than ever before. A move towards open, reproducible science has provided impetus for developing population genetic analysis tools in R. We previously contributed the R package *poppr* specifically addressing issues with analysis of clonal populations. In this paper we provide several significant extensions to *poppr* with a focus on large, genome-wide SNP data. Specifically, we provide several new functionalities including the new function `mlg.filter` to define clone boundaries allowing for inspection and definition of what is a clonal lineage, a sliding-window analysis of the index of association, modular bootstrapping of any genetic distance, and analyses across any level of hierarchies.

Keywords: clonality, population genetics, bootstrap, index of association, hierarchical analysis, sliding window

INTRODUCTION

To paraphrase Dobzhansky, nothing in the field of plant-microbe interactions makes sense except in the light of population genetics (Dobzhansky, 1973). Genetic forces such as selection and drift act on alleles in a population. Thus, a true understanding of how plant pathogens evolve and adapt to crops, fungicides, or other factors, can only emerge in the context of population level phenomena given the demographic history of populations (McDonald and Linde, 2002; Grnwald and Goss, 2011; Milgroom et al., 1989). The field of population genetics, in the era of whole genome resequencing, provides unprecedented power to describe the evolutionary history and population processes that drive coevolution between pathogens and hosts. This powerful field thus critically enables effective deployment of R genes, design of pathogen informed plant resistance breeding programs, and implementation of fungicide rotations that minimize emergence of resistance.

26 Most computational tools for population genetics are based on concepts developed for sexual model
27 organisms. Populations that reproduce clonally or are polyploid are thus difficult to characterize using
28 classical population genetic tools because theoretical assumptions underlying the theory are violated. Yet,
29 many plant pathogen populations are at least partially clonal if not completely clonal (Milgroom, 1996;
30 Anderson and Kohn, 1995). Thus, development of tools for analysis of clonal or polyploid populations is
31 needed.

32 Genotyping by sequencing and whole genome resequencing provide the unprecedented ability to
33 identify thousands of single nucleotide polymorphisms (SNPs) in populations (Elshire et al., 2011; Luikart
34 et al., 2003; Davey et al., 2011). With traditional marker data (e.g., SSR, AFLP) a clone was typically
35 defined as a unique multilocus genotype (MLG) (Grnwald and Hoheisel, 2006; Falush et al., 2003; Goss
36 et al., 2009; Cooke et al., 2012; Taylor and Fisher, 2003). Availability of large SNP data sets provides new
37 challenges for data analysis. These data are based on reduced representation libraries and high throughput
38 sequencing with moderate sequencing depth which invariably results in substantial missing data, error in
39 SNP calling due to sequencing error, lack of read depth or other sources of spurious allele calls (Mastretta-
40 Yanes et al., 2015). It is thus not clear what a clone is in large SNP data sets and novel tools are required
41 for definition of clone boundaries.

42 The research community using the R statistical and computing language (R Core Team, 2015) has
43 developed a plethora of new resources for population genetic analysis (Paradis, 2010; Jombart, 2008).
44 Recently, we introduced the R package *poppr* specifically developed for analysis of clonal populations
45 (Kamvar et al., 2014b). *Poppr* previously introduced several novel features including the ability to conduct
46 a hierarchical analysis across unlimited hierarchies, test for linkage association, graph minimum spanning
47 networks or provide bootstrap support for Bruvo's distance in resulting trees. *Poppr* has been rapidly
48 adopted and applied to a range of studies including for example horizontal transmission in leukemia of
49 clams (Metzger et al., 2015), study of the vector-mediated parent- to-offspring transmission in an avian
50 malaria-like parasite (Chakarov et al., 2015), and characterization of the emergence of the invasive forest
51 pathogen *Hymenoscyphus pseudoalbidus* (Gross et al., 2014).

52 Here, we introduce *poppr* 2.0, which provides a major update to *poppr* (Kamvar et al., 2014b) including
53 novel tools for analysis of clonal populations specifically addressing large SNP data. Significant novel
54 tools include functions for calculating clone boundaries and collapsing individuals into user- specified
55 clones based on genetic distance, sliding window analyses, genotype accumulation curves, reticulations
56 in minimum spanning networks, and bootstrapping for any genetic distance.

IMPLEMENTATIONS AND EXAMPLES

CLONAL IDENTIFICATION

57 As highlighted in previous work, clone correction is an important component of population genetic
58 analysis of organisms that have cryptic growth or are known to reproduce asexually (Kamvar et al., 2014b;
59 Milgroom, 1996; Grnwald et al., 2003). This method is a partial correction for bias that affects metrics
60 that rely on allele frequencies assuming panmixia. It was initially designed for data with only a handful
61 of markers. With the advent of large-scale sequencing and reduced-representation libraries, it has become
62 easier to sequence tens of thousands of markers from hundreds of individuals (Elshire et al., 2011; Davey
63 et al., 2011; Davey and Blaxter, 2010). With this larger number of markers, the genetic resolution is much
64 greater, but the chance of genotyping error is also greatly increased (Mastretta-Yanes et al., 2015). Taking
65 this fact and occasional somatic mutations into account, it would be impossible to separate true clones
66 from independent individuals by just comparing what multilocus genotypes are different. We introduce
67 a new method for collapsing unique multilocus genotypes determined by naive string comparison into
68 multilocus lineages utilizing any genetic distance given three different clustering algorithms: farthest
69 neighbor, nearest neighbor, and UPGMA (Sokal, 1958).

These clustering algorithms act on a distance matrix that is either provided by the user or generated via a function that will calculate a distance from genclone objects such as `bruvo.dist`, which in particular applies to any level of ploidy (Bruvo et al., 2004). All algorithms have been implemented in C and utilize the OpenMP framework for optional parallel processing (Dagum and Menon, 1998). Default is the conservative farthest neighbor algorithm (Fig. 1A), which will only cluster samples together if all samples in the cluster are at a distance less than the given threshold. By contrast, the nearest neighbor algorithm will have a chaining effect that will cluster samples akin to adding links on a chain where a sample can be included in a cluster if all of the samples have at least one connection below a given threshold (Fig. 1C). The UPGMA, or average neighbor clustering algorithm is the one most familiar to biologists as it is often used to generate ultra-metric trees based on genetic distance (Fig. 1B). This algorithm will cluster by creating a representative sample per cluster and joining clusters if these representative samples are closer than the given threshold.

We utilize data from the microbe *Phytophthora infestans* to show how the `mlg.filter` function collapses multilocus genotypes with Bruvo's distance assuming a genome addition model (Bruvo et al., 2004). *P. infestans* is the causal agent of potato late blight originating from Mexico and spread to Europe in the mid 19th century (Goss et al., 2014; Li et al., 2013; Lees et al., 2006). *P. infestans* reproduces both clonally and sexually. The clonal lineages of *P. infestans* have been formally defined into 18 separate clonal lineages using a combination of various molecular methods including AFLP and microsatellite markers (Lees et al., 2006). For these data, we used `mlg.filter` to detect all of the distance thresholds at which 18 multilocus lineages would be resolved. We used these thresholds to define multilocus lineages and create contingency tables and dendograms to determine how well the multilocus lineages were detected.

For the *P. infestans* population, the three algorithms were able to detect 18 multilocus lineages at different distance thresholds (Fig. 2). Contingency tables between the described multilocus genotypes and the genotypes defined by distance show that most of the 18 lineages were resolved, except for US-8, which is polytomous (Table 1).

We utilized simulated data constructed using the `glSim` function in *adegenet* (Jombart and Ahmed, 2011) to obtain a SNP data set for demonstration. Two diploid data sets were created, each with 10k SNPs (25% structured into two groups) and 200 samples with 10 ancestral populations of even sizes. Clones were created in one data set by marking each sample with a unique identifier and then randomly sampling with replacement. It is well documented that reduced-representation sequencing can introduce several erroneous calls and missing data (Mastretta-Yanes et al., 2015). To reflect this, we mutated SNPs at a rate of 10% and inserted an average of 10% missing data for each sample after clones were created, ensuring that no two sequences were alike. The number of mutations and missing data per sample were determined by sampling from a Poisson distribution with $\lambda = 1000$. After pooling, 20% of the data set was randomly sampled for analysis. Genetic distance was obtained with the function `bitwise.dist`, which calculates the fraction of different sites between samples equivalent to Provesti's distance, counting missing data as equivalent in comparison (Prevosti et al., 1975).

All three filtering algorithms were run with a threshold of 1, returning a numeric vector of length $n - 1$ where each element represented a threshold at which two samples/clusters would join. Since each data set would have varying distances between samples, the clonal boundary threshold was defined as the midpoint of the largest gap between two thresholds that collapsed less than 50% of the data.

Out of the 100 simulations run, we found that across all methods, detection of duplicated samples had $\sim 98\%$ true positive fraction and $\sim 0.8\%$ false positive fraction indicating that this method is robust to simulated populations.

MINIMUM SPANNING NETWORKS WITH RETICULATION

In its original iteration, *poppr* introduced minimum spanning networks that were based on the *igraph* function `minimum.spanning.tree` (Csardi and Nepusz, 2006). This algorithm produces a minimum

117 spanning tree with no reticulations where nodes represent individual MLGs. In other minimum spanning
118 network programs, reticulation is obtained by calculating the minimum spanning tree several times and
119 returning the set of all edges included in the trees. Due to the way *igraph* has implemented Prim's
120 algorithm, it is not possible to utilize this strategy, thus we implemented an internal C function to walk
121 the space of minimum spanning trees based on genetic distance to connect groups of nodes with edges of
122 equal weight.

123 To demonstrate the utility of minimum spanning networks with reticulation, we used two clonal data
124 sets: the H3N2 flu virus data from the *aedgenet* package using years of each epidemic as the population
125 factor, and *Phytophthora ramorum* data from Nurseries and Oregon forests (Jombart et al., 2010; Kamvar
126 et al., 2014a). Minimum spanning networks were created with and without reticulation using the *poppr*
127 functions *diss.dist* and *bruvo.msn* for the H3N2 and *P. ramorum* data, respectively (Kamvar et
128 al., 2014b; Bruvo et al., 2004). To detect mlg clusters, the infoMAP community detection algorithm was
129 applied with 10,000 trials as implemented in the R package *igraph* version 0.7.1 utilizing genetic distance
130 as edge weights and number of samples in each MLG as vertex weights (Csardi and Nepusz, 2006; Rosvall
131 and Bergstrom, 2008).

132 To evaluate the results, we compared the number, size, and entropy (H) of the resulting communities
133 as we expect a highly clonal organism with low genetic diversity to result in a few, large communities.
134 We also created contingency tables of the community assignments with the defined populations and used
135 those to calculate entropy using Shannon's index with the function *diversity* from the R package
136 *vegan* version 2.2-1 (Oksanen et al., 2015; Shannon, 2001). A low entropy indicates presence of a few
137 large communities whereas high entropy indicates presence of many small communities.

138 The infoMAP algorithm revealed 63 communities with a maximum community size of 77 and $H = 3.56$
139 for the reticulate network of the H3N2 data and 117 communities with a maximum community size of
140 26 and $H = 4.65$ for the minimum spanning tree. The entropy across years was greatly decreased for all
141 populations with the reticulate network compared to the minimum spanning tree (Fig. 3).

142 Graph walking of the reticulated minimum spanning network of *P. ramorum* by the infoMAP algorithm
143 revealed 16 communities with a maximum community size of 13 and $H = 2.60$. The un-reticulated
144 minimum spanning tree revealed 20 communities with a maximum community size of 7 and $H = 2.96$.
145 In the ability to predict Hunter Creek as belonging to a single community, the reticulated network was
146 successful whereas the minimum spanning tree separated one genotype from that community. The entropy
147 for the reticulated network was lower for all populations except for the coast population (supplementary
148 information).

BOOTSTRAPPING

149 Assessing population differentiation through methods such as G_{st} , AMOVA, and Mantel tests relies on
150 comparing samples within and across populations (Nei, 1973; Excoffier et al., 1992; Mantel, 1967).
151 Confidence in distance metrics is related to the confidence in the markers to accurately represent the
152 diversity of the data. Especially true with microsatellite markers, a single hyper-diverse locus can make a
153 population appear to have more diversity based on genetic distance. Using a bootstrapping procedure of
154 randomly sampling loci with replacement when calculating a distance matrix provides support for clades
155 in hierarchical clustering.

156 Data in genind and genpop objects are represented as matrices with individuals in rows and alleles in
157 columns (Jombart, 2008). This gives the advantage of being able to use R's matrix algebra capabilities to
158 quickly calculate genetic distance. Unfortunately, this also means that bootstrapping is a non-trivial task
159 as all alleles at a single locus need to be sampled together. To remedy this, we have created an internal S4
160 class called "bootgen", which extends the internal "gen" class from *aedgenet*. This class can be created
161 from any genind, genclone, or genpop object, and allows loci to be sampled with replacement. To further
162 facilitate bootstrapping, a function called *aboot*, which stands for "any boot", is introduced that will
163 bootstrap any genclone, genind, or genpop object with any genetic distance that can be calculated from it.

164 To demonstrate calculating a dendrogram with bootstrap support, we used the *poppr* function *aboot*
 165 on population allelic frequencies derived from the data set *microbov* in the *adegenet* package with 1000
 166 bootstrap replicates (Jombart, 2008; Lalo et al., 2007). The resulting dendrogram shows bootstrap support
 167 values > 50% (Fig. 4).

```
library("poppr")
data("microbov", package = "adegenet")
strata(microbov) <- data.frame(other(microbov))
setPop(microbov) <- ~coun/spe/breed
bov_pop <- genind2genpop(microbov, quiet = TRUE)

set.seed(20150428)
pop_tree <- aboot(bov_pop, sample = 1000, cutoff = 50, quiet = TRUE)
```

GENOTYPE ACCUMULATION CURVE

168 Analysis of population genetics of clonal organisms often borrows from ecological methods such as
 169 analysis of diversity within populations (Milgroom, 1996; Arnaud-Hanod et al., 2007; Grnwald et al.,
 170 2003). When choosing markers for analysis, it is important to make sure that the observed diversity in your
 171 sample will not appreciably increase if an additional marker is added (Arnaud-Hanod et al., 2007). This
 172 concept is analogous to a species accumulation curve, obtained by rarefaction. The genotype accumulation
 173 curve in *poppr* is implemented in the function *genotype_curve*. The curve is constructed by randomly
 174 sampling x loci and counting the number of observed MLGs. This repeated r times for 1 locus up to $n - 1$
 175 loci, creating $n - 1$ distributions of observed MLGs.

176 The following code example demonstrates the genotype accumulation curve for data from Everhart and
 177 Scherm (2015) showing that these data reach a small plateau and have a greatly decreased variance with
 178 12 markers, indicating that there are enough markers such that adding more markers to the analysis will
 179 not create very many new genotypes (Fig. 5).

```
library("poppr")
library("ggplot2")
data("monpop", package = "poppr")

set.seed(20150428)
genotype_curve(monpop, sample = 1000, quiet = TRUE)
p <- last_plot() + theme_bw() # get the last plot
p + geom_smooth(aes(group = 1)) # plot with a trendline
```

INDEX OF ASSOCIATION

180 The index of association (I_A) is a measure of multilocus linkage disequilibrium that is most often used
 181 to detect clonal reproduction within organisms that have the ability to reproduce via sexual or asexual
 182 processes (Brown et al., 1980; Smith et al., 1993; Milgroom, 1996). It was standardized in 2001 as \bar{r}_d
 183 by Agapow and Burt (2001) to address the issue of scaling with increasing number of loci. This metric is
 184 typically applied to traditional dominant and co-dominant markers such as AFLPs, SNPs, or microsatellite
 185 markers. With the advent of high throughput sequencing, SNP data is now available in a genome-wide
 186 context and in very large matrices including thousands of SNPs. Thus, the likelihood of finding mutations
 187 within two individuals of a given clone increases and tools are needed for defining clone boundaries.
 188 For this reason, we devised two approaches using the index of association for large numbers of markers
 189 typical for population genomic studies. Both functions utilize *adegenet*'s "genlight" object class, which
 190 efficiently stores 8 binary alleles in a single byte (Jombart and Ahmed, 2011). As calculation of the \bar{r}_d

191 requires distance matrices of absolute number of differences, we utilize a function that calculates these
192 distances directly from the compressed data called `bitwise.dist`.

193 The first approach is a sliding window approach implemented in the function `win.ia`. It utilizes the
194 position of markers in the genome to calculate \bar{r}_d among any number of SNPs found within a user-
195 specified windowed region. It is important that this calculation utilize \bar{r}_d as the number of loci will be
196 different within each window (Agapow and Burt, 2001). This approach would be suited for a quick
197 calculation of linkage disequilibrium across the genome that can detect potential hotspots of LD that
198 could be investigated further with more computationally intensive methods assuming that the number of
199 samples << the number of loci.

200 As it would necessarily focus on loci within a short section of the genome that may or may not
201 be recombining, a sliding window approach would not be good for utilizing \bar{r}_d as a test for clonal
202 reproduction. A remedy for this is implemented in the function `samp.ia`, which will randomly sample
203 m loci, calculate \bar{r}_d , and repeat r times, thus creating a distribution of expected values of \bar{r}_d .

204 To demonstrate the sliding window and random sampling of \bar{r}_d with respect to clonal populations, we
205 simulated two populations containing 1,100 neutral SNPs for 100 diploid individuals under the same
206 initial seed. One population had individuals randomly sampled with replacement, representing the clonal
207 population. After sampling, both populations had 5% random error and 1% missing data independently
208 propagated across all samples. On average, we obtained a higher value of \bar{r}_d for the clonal population
209 compared to the sexual population for both methods (Fig. 6).

DATA FORMAT UPDATES: POPULATION STRATA AND HIERARCHIES

210 Assessments of population structure through methods such as hierarchical F_{st} (Goudet, 2005) and
211 AMOVA (Michalakis and Excoffier, 1996) require hierarchical sampling of populations across space
212 or time (Linde et al., 2002; Everhart and Scherm, 2015; Grnwald and Hoheisel, 2006). With clonal
213 organisms, basic practice has been to clone-censor data to avoid downward bias in diversity due to
214 duplicated genotypes that may or may not represent different samples (Milgroom, 1996). This correction
215 should be performed with respect to a population hierarchy to accurately reflect the biology of the
216 organism. Traditional data structures for population genetic data in most analysis tools allow for only
217 one level of hierarchical definition. The investigator thus had to provide the data set for analysis at each
218 hierarchical level.

219 To facilitate handling hierarchical and multilocus genotypic metadata, `poppr` version 1.1 introduced
220 a new S4 data object called “genclone”, extending `aedegeenet`’s “genind” object. The genclone object
221 formalized the definitions of multilocus genotypes and population hierarchies by adding two slots called
222 “mlg” and “hierarchy” that carried a numeric vector and a data frame, respectively. These new slots allow
223 for increased efficiency and ease of use by allowing these metadata to travel with the genetic data. The
224 hierarchy slot in particular contains a data frame where each column represents a separate hierarchical
225 level. This is then used to set the population factor of the data by supplying a hierarchical formula
226 containing one or more column names of the data frame in the hierarchy slot.

227 The functionality represented by the hierarchy slot has now been migrated to the `aedegeenet` package,
228 version 2.0 to allow hierarchical analysis in `aedegeenet`, `poppr`, and other dependent packages. The prior
229 `poppr` hierarchy slot and methods have now been renamed `strata` in `aedegeenet`. This migration
230 provides end users with a broader ability to analyze data hierarchically in R across packages.

AVAILABILITY

231 As of this writing, the `poppr` R package version 2.0 containing all of the features described here
232 is located at <https://github.com/grunwaldlab/poppr/tree/2.0-rc>. It is necessary
233 to install `aedegeenet` 2.0 before installing `poppr`. It can be found at <https://github.com/>

234 thibautjombart/adegenet. Both of these can be installed via the R package *devtools* (Wickham
235 and Chang, 2015):

```
library("devtools")
install_github("thibautjombart/adegenet")
install_github("grunwaldlab/poppr@2.0-rc")
```

236 Several population genetics packages in R are currently going through a major upgrade and have not
237 yet been updated in CRAN. We will push *poppr* 2.0 to CRAN, once all other reverse dependent packages
238 have been updated.

DISCUSSION

239 Genomic data has become more readily accessible due to advances in low-cost sequencing technology.
240 Many tools have been developed or adapted to these data, but most of them were designed with sexual
241 populations in mind. Particularly important is the implementation of \bar{r}_d for genomic data (Agapow and
242 Burt, 2001). Random sampling of loci across the genome can give an expected distribution of \bar{r}_d , which
243 is expected to have a mean of zero for panmictic populations. Additionally, due to the fact that it acts
244 on multiple loci, is not affected by the number of loci sampled, and has the ability to detect population
245 structure, \bar{r}_d is well suited to sliding window analyses and has the potential to be applied to non-clonal
246 populations.

247 Clustering multilocus genotypes into multilocus lineages based on genetic distances is a non-trivial task.
248 Moreover, this has not previously been implemented for genomic data for clonal populations. Perhaps
249 highlighting the fact that many of the features presented in this paper are not exclusive to genomic
250 data is the fact that this method of clonal assignment has been available in the programs GENCLONE
251 and GENODIVE (Arnaud-Hanod et al., 2007; Meirmans and Van Tienderen, 2004). Our method with
252 `mlg.filter` builds upon this idea and allows the user to choose between three different approaches for
253 clustering MLGs. As shown in Fig. 2, it is clear that the choice of clustering algorithm has an impact on
254 the data, where a genetic distance cutoff of 0.1 would be the difference between 14 MLLs and 17 MLLs
255 for nearest neighbor and UPGMA clustering, respectively (Fig. 2). The option to choose the clustering
256 algorithm gives the user the ability to choose what is biologically relevant to their populations.

257 Multilocus genotypes that have been clustered can then be visualized in minimum spanning networks.
258 Reticulate minimum spanning networks are very important for clonal organisms where a minimum
259 spanning tree would become a chain, implying that the clones were derived in a progressive and linear
260 fashion. This presents but one potential scenario for clonal organisms, but does not account for any other
261 biologically relevant process. Reticulations in the minimum spanning networks allow for a representation
262 of uncertainty that goes along with clonal organisms. The current implementation in *poppr* has been
263 successfully used in analyses such as reconstruction of the *P. ramorum* epidemic in Curry County, OR
264 (Kamvar et al., 2014a, 2015). Reticulated networks also allow for the application of graph community
265 detection algorithms such as the infoMAP algorithm (Rosvall and Bergstrom, 2008). As shown in the *P.*
266 *ramorum* and H3N2 data, while it is possible to utilize these graph walking algorithms on non-reticulate
267 minimum spanning trees, the results derived from these are limited to explain populations derived from
268 serial cloning events.

269 Implementing these methods in R and hosting the code free and open on GitHub has given us the ability
270 to tailor our tools to the needs of the researchers who use them.

 293 the *adegenet* package representing flu epidemics from 2001 to 2006 without reticulation (A) and with
 294 reticulation (B) (Jombart, 2008; Jombart et al., 2010). Each node represents a unique multilocus genotype,
 295 colors represent epidemic year, and edge color represents absolute genetic distance. (C) Shannon entropy
 296 values for population assignments compared with communities determined by the infoMAP algorithm on
 297 (A) and (B). (D) Graphic reproduced from Jombart et al. (2010) showing that the 2006 epidemic does not
 298 cluster neatly with the other years.

FIGURE 4

299 UPGMA dendrogram generated from Nei's genetic distance on 15 breeds of *Bos taurus* (BT) or *Bos*
 300 *indicus* (BI) from Africa (AF) or France (FR). These data are from Lalo et al. (2007). Node labels represent
 301 bootstrap support > 50% out of 1,000 bootstrap replicates.

FIGURE 5

302 Genotype accumulation curve for 694 isolates of the peach brown rot pathogen, *Monilinia fructicola*
 303 genotyped over 13 loci from Everhart and Scherm (2015). The horizontal axis represents the number
 304 of loci randomly sampled without replacement up to $n - 1$ loci, the vertical axis shows the number of
 305 multilocus genotypes observed, up to 262, the number of unique multilocus genotypes in the data set. The
 306 red dashed line represents 90% of the total observed multilocus genotypes. A trendline (blue) has been
 307 added using the *ggplot2* function *stat_smooth*.

FIGURE 6

308 (A) Sliding window analysis of the standardized index of association (\bar{r}_d) across a simulated 1.1×10^4 nt
 309 chromosome containing 1,100 variants among 100 individuals. Each window analyzed variants within
 310 500nt chunks. The black line refers to the clonal and the blue line to the sexual populations. (B) boxplots
 311 showing 100 random samples of 50 variants to calculate a distribution of \bar{r}_d for the clonal (red) and sexual
 312 (blue) populations. Each box is centered around the mean, with whiskers extending out to 1.5 times the
 313 interquartile range. The median is indicated by the center line. (A) and (B) are plotted on the same y-axis.

TABLE 1

314 Contingency table comparing multilocus lineages assigned based on average neighbor clustering
 315 (columns) vs. multilocus lineages defined in Li et al. (2013) and Lees et al. (2006).
